Metropolis Hastings Algorithm

Michael Rose

Question

Suppose we have data $X_1, ..., X_n$ which we believe come from a normal distribution with mean θ and variance 1. Suppose we are uncertain about θ , and for us θ has the following Cauchy Distribution:

$$f(\theta) = \frac{1}{\pi(1+\theta^2)}, -\infty < \theta < \infty$$

This is a special form of the Cauchy called the standard Cauchy Distribution with parameters $x_0 = 0, \gamma = 1$.

We will write a Metropolis Hastings Algorithm whose limiting distribution is our posterior distribution.

First lets simulate some data

```
# choose a cauchy sample for mean
theta_x <- rcauchy(1,location = 0, scale = 1)
theta_x
## [1] -2.191831
# generate samples
data_y <- rnorm(n = 1000, mean = theta_x, sd = 1)</pre>
```

Now we can create our metropolis algorithm:

The Metropolis Algorithm calls for θ_{prop} to be sampled from a symmetric proposal distribution centered at the current parameter value, θ_{curr} . For this task we will use $\theta_{prop} \sim \text{Normal}(\theta_{curr}, \sigma^2)$.

The proposal distribution is separate and distinct from either the prior or posterior distribution for the parameter. The proposal distribution's sole purpose is to give candidate parameter values to try and potentially accept as a valid sample from the posterior distribution of θ .

- samples is the number of samples we want to draw from the posterior distribution and determines the length of the resulting MCMC chain
- the ta_start gives us a θ to start the algorithm
- sd is the standard deviation of the proposal distribution

Within the function, we construct a for loop that repeatedly draws θ_{prop} from a standard normal proposal distribution (using rnorm). It then computes the ratio of Bayes' numerators and carries out the accept / reject logic. We store the results in a vector called posterior_thetas which are initialized to NA.

```
metropolis_algo <- function(samples, theta_start, sd){
    # declarations
    theta_curr <- theta_start
    # vector of NAs to store sampled parameters
    posterior_thetas <- rep(NA, times = samples)

for (i in 1:samples){
    # proposal distribution
    theta_prop <- rnorm(n = 1, mean = theta_curr, sd = sd)

    # if proposed parameter is outside range, set to current value. Else keep proposed value
    theta_prop <- ifelse((theta_prop < 0 | theta_prop > 1), theta_curr, theta_prop)
```

```
# bayes numerators
posterior_prop <- dcauchy(theta_prop, location = 0, scale = 1) *
    dnorm(data_y, mean = theta_prop, sd = 1)
posterior_curr <- dcauchy(theta_curr, location = 0, scale = 1) *
    dnorm(data_y, mean = theta_curr, sd = 1)

# calculate probability of accepting
p_accept_theta_prop <- min(posterior_prop / posterior_curr, 1.0)

rand_unif <- runif(n=1)

# probabilistically accept proposed theta
theta_select <- ifelse(p_accept_theta_prop > rand_unif, theta_prop, theta_curr)
posterior_thetas[i] <- theta_select

# reset theta_curr for the next iteration of the loop
theta_curr <- theta_select
}
return(posterior_thetas)
}</pre>
```

Now we can try 10,000 samples with a starting value of 0.9 and a sd for our normal proposal distribution of 0.05

```
set.seed(888)
posterior_thetas <- metropolis_algo(samples = 10000, theta_start = 0.9, sd = 0.05)</pre>
```

Lets take a look at the kernel density estimate of the posterior.

Kernel Density Plot for $\boldsymbol{\theta}$
